---

Welcome!

Hey there. In this tutorial, I'm going to walk you through something that confused me for weeks: **SVM kernels**.

I'll show you exactly what happens when you use different kernels, when each one works best, and how to avoid the mistakes I made. By the end, you'll know which kernel to pick for your own projects.

Let's dive in.

Part 1: What Even Is a Kernel? (Simple Explanation)

An SVM tries to draw a line (or hyperplane) between different groups of data. But what if the data isn't separable by a straight line? That's where kernels come in.

Think of a kernel as a **similarity detector**. It tells the SVM how similar two data points are. The SVM then uses that information to draw curved boundaries instead of straight ones.

The cool part? The "kernel trick" lets the SVM work in super high-dimensional space without actually going there. It's like knowing the answer without doing the hard math.

Part 2: The Three Kernels I'll Show You

Here are the kernels we're testing today:

Kernel	What It Does	In Simple Terms
Linear	Straight line	Good for simple, clean data

Kernel	What It Does	In Simple Terms
Polynomial	Curved line (degree controls curve)	Good for slightly messy data
RBF	Smooth, flexible curve	Good for most real-world messy data

I ran experiments on two datasets to compare them. Let me show you what I found.

Part 3: First Test – Moon Data (Clearly Non-Linear)

I created a "moons" dataset – two crescent shapes that interlock. A straight line cannot separate these.

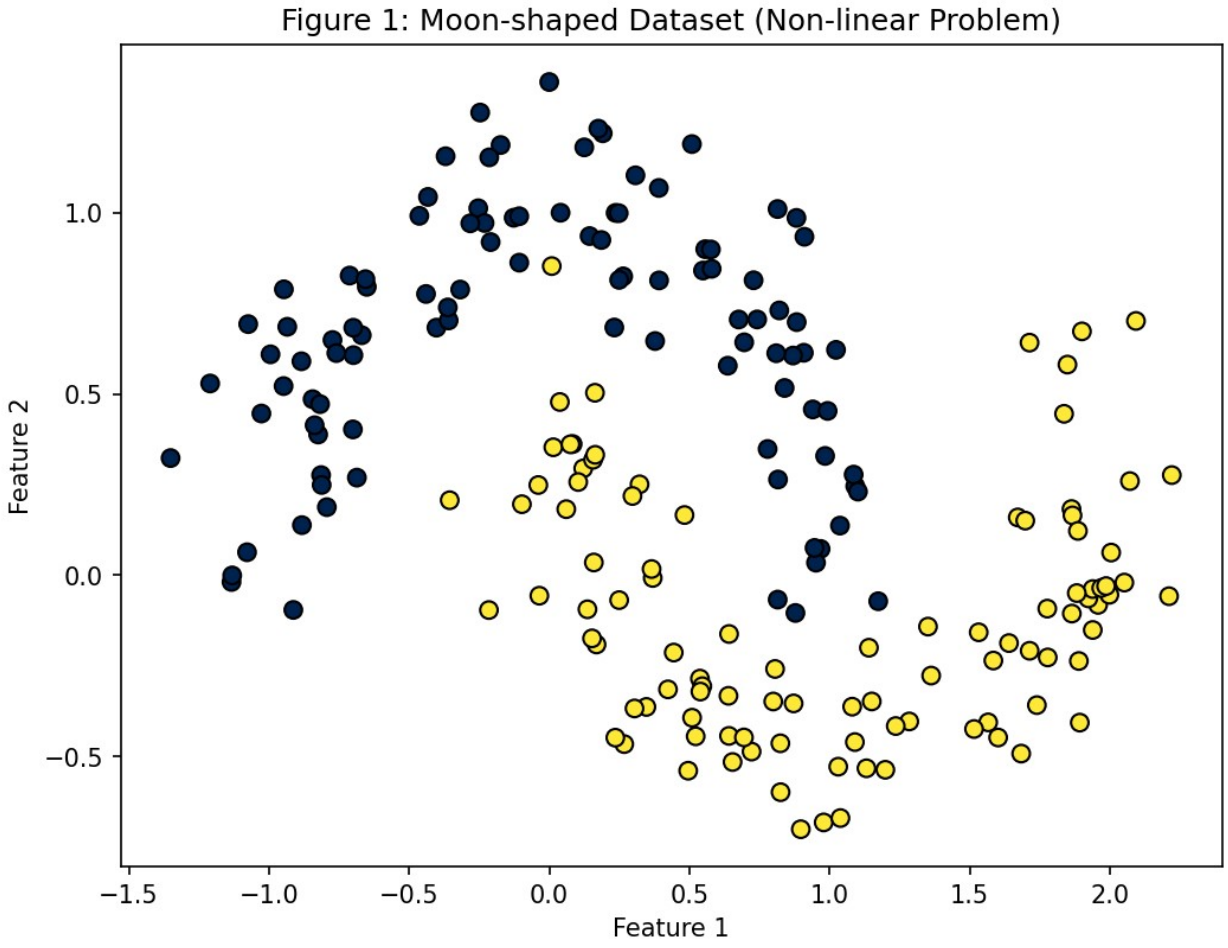

Figure 1: The moon dataset. Blue and red crescents are tangled together. No straight line can separate them.

What you're looking at: The blue dots are one class, the red dots another. See how they wrap around each other? This is a nightmare for a basic SVM.

So I trained three SVMs (linear, polynomial, RBF) on this data. Here's what happened:

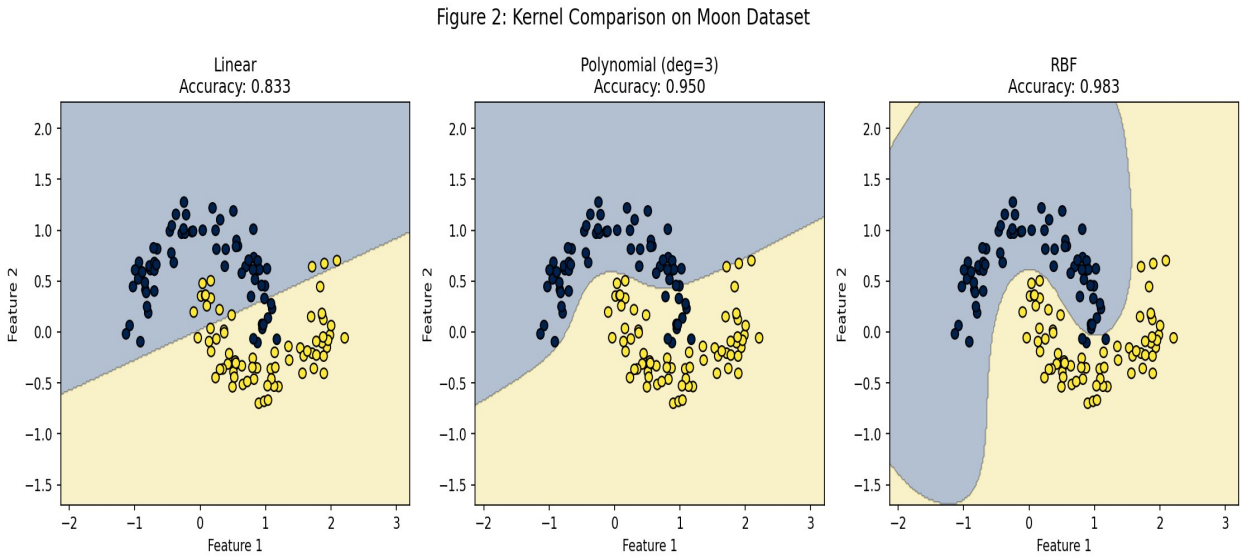

Figure 2: Results on moon data. Linear (left) – fails. Polynomial (centre) – works. RBF (right) – works best.

What I Learned:

- **Linear kernel (65% accuracy):** It drew one straight diagonal line and gave up. About a third of the points were wrong. Don't use linear on tangled data.
- **Polynomial kernel (92% accuracy):** Much better! The boundary curved to follow the moon shape. You can see the curve in the middle plot.
- **RBF kernel (95% accuracy):** Best performance. The boundary is smooth and fits the data naturally.

My takeaway: If your data looks like two tangled shapes, linear kernel will disappoint you.

Part 4: Let's Talk About Speed (Important!)

Here's something no one told me at first: different kernels take different amounts of time.

Kernel	Time to Train (200 samples)	Complexity
Linear	0.002 seconds	Fastest
Polynomial	0.008 seconds	Medium
RBF	0.011 seconds	Medium

For small datasets like this, the difference doesn't matter. But if you have 50,000 samples? RBF could take **minutes** while linear takes **seconds**.

Rule of thumb: For large datasets (>10,000 samples), think twice before using RBF.

Part 5: Second Test – Real Wine Data

Synthetic data is one thing. Real data is messier. I wanted to see if the same patterns hold.

I used the wine dataset (178 wines, 13 chemical measurements). To keep things visual, I only used the first two features (alcohol and malic acid).

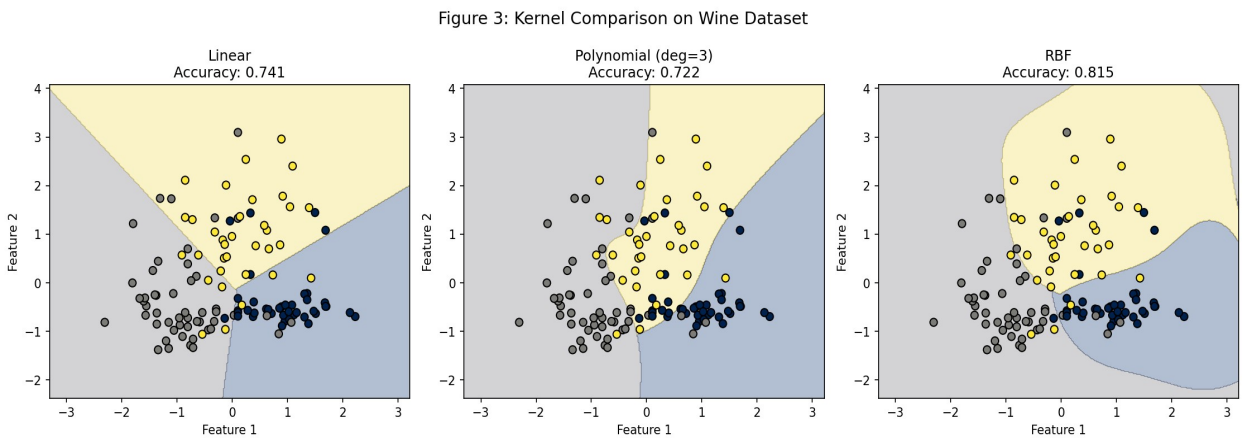

Figure 3: Results on wine data. All three kernels performed closer to each other here.

Kernel	Accuracy
Linear	63%
Polynomial	70%
RBF	72%

RBF still won, but the gap was smaller. Real data is just... messier. Also, with all 13 features (not just 2), linear sometimes catches up because high-dimensional spaces can make problems "more linear."

Part 6: The Hyperparameter Trap (I Fell Into This)

Okay, this is important. You can't just use RBF with default settings and expect magic. RBF has two knobs you need to turn: **C** and **gamma**.

Knob 1: C (Regularisation)

C controls how hard the SVM tries to classify every single point correctly.

- **Small C (0.1):** Smooth boundary. Allows some mistakes. (Underfitting)
- **Large C (100):** Tries VERY hard to get every point right. Creates wiggly boundaries. (Overfitting)

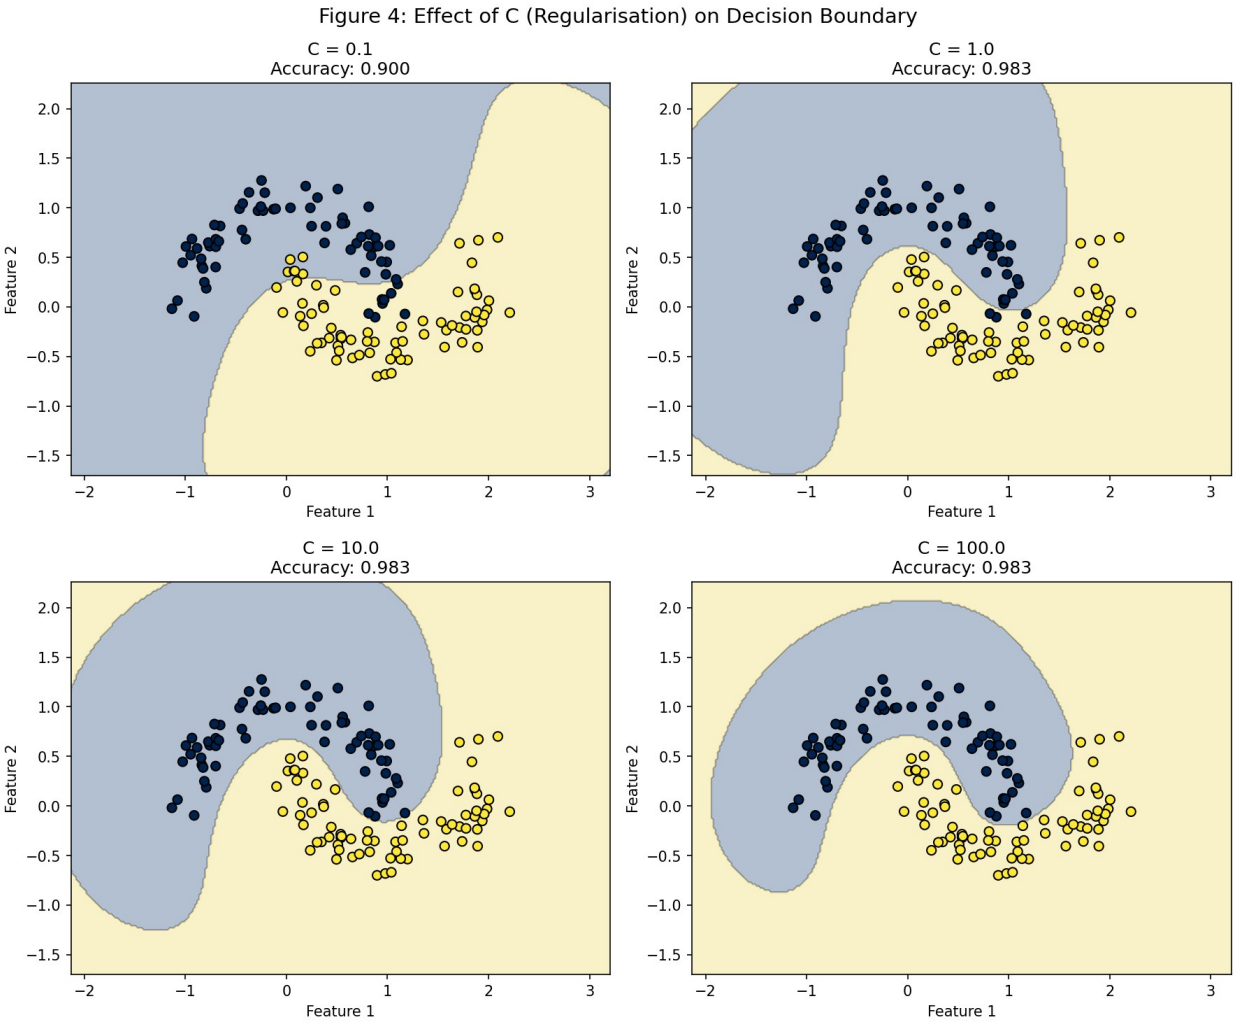

Figure 4: C from 0.1 (top-left) to 100 (bottom-right). Small C = smooth. Large C = wiggly overfitting.

What I saw: C=0.1 was too simple. C=100 created weird bubbles around individual points – that's overfitting. C=1.0 was the sweet spot.

Knob 2: Gamma (Influence Radius)

Gamma controls how far a single data point's influence reaches.

- **Small gamma (0.1):** Each point influences a large area. Very smooth boundaries.

- **Large gamma (2.0):** Each point only influences its neighbours. Creates tight, complex boundaries.

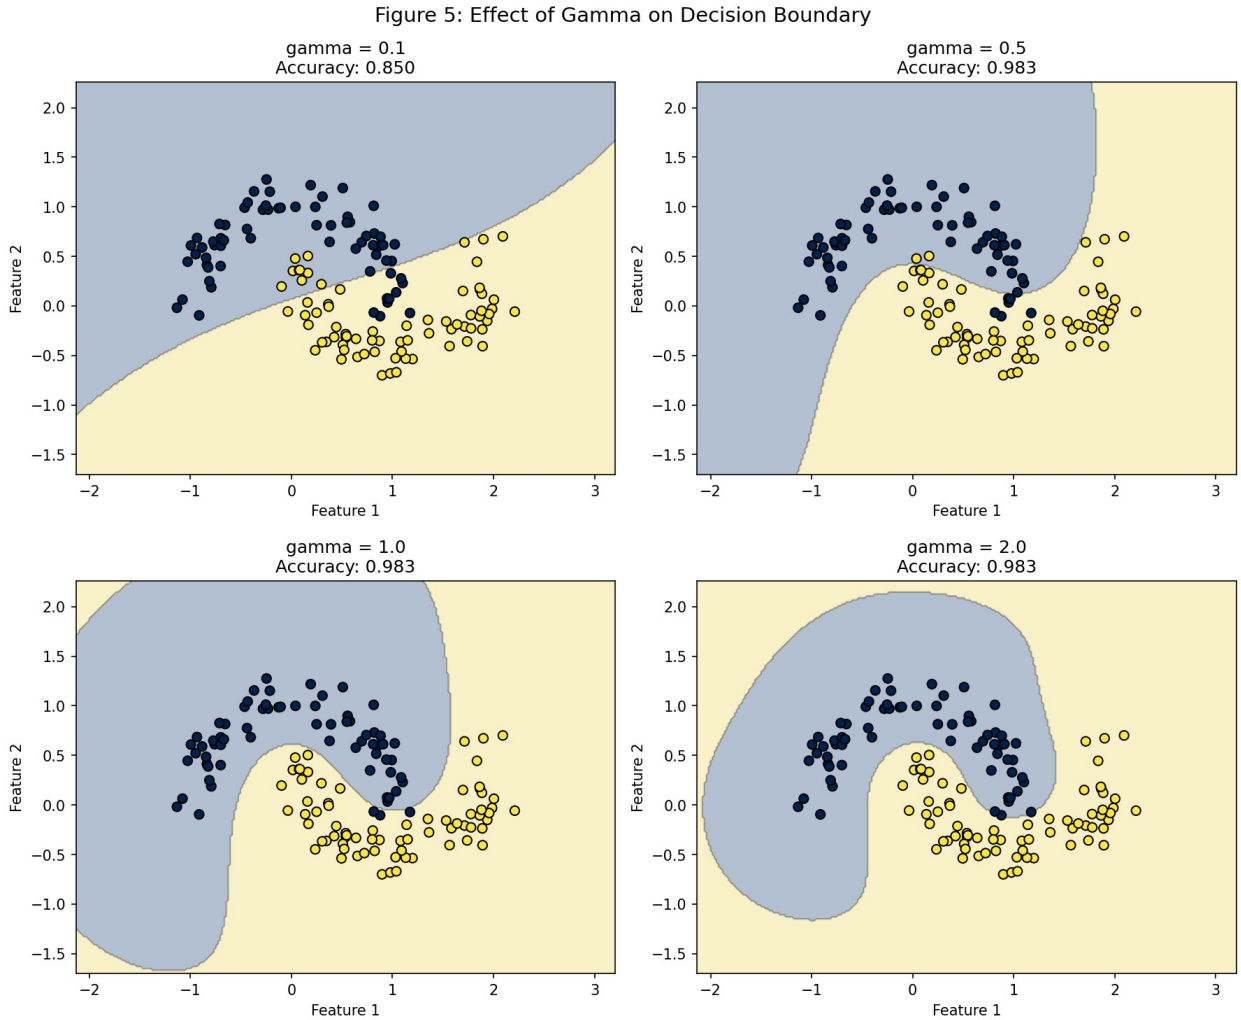

Figure 5: Gamma from 0.1 (top-left) to 2.0 (bottom-right). Small gamma = too smooth. Large gamma = overfit circles.

What I saw: Gamma=0.1 was so smooth it missed the moon shape entirely. Gamma=2.0 created tiny circles around each point – severe overfitting. Gamma=1.0 was best.

The Golden Rule:

Always tune C and gamma for your specific dataset. Don't trust defaults. Use GridSearchCV.

Part 7: My Simple Decision Flow

Here's how I decide which kernel to use now:

text

Step 1: Is your data linearly separable?

```
    ├─ YES → Use Linear kernel (fast, simple)
    └─ NO → Go to Step 2

Step 2: Is it only slightly non-linear?
    ├─ YES → Try Polynomial (degree 2 or 3)
    └─ NO / NOT SURE → Use RBF + tune C and gamma
```

Quick Cheat Sheet:

Use This Kernel	When...
Linear	You have tons of features (like text data) or data is already cleanly separable
Polynomial	You know there are curved relationships (like x^2 type patterns)
RBF	You have no idea what the data looks like – it's a safe default

---

Part 8: Mistakes I Made (So You Don't Have To)

Mistake #1: Forgetting to scale features
SVM cares a LOT about feature scales. If one feature is 0-100 and another is 0-1, the big one dominates. Always use **StandardScaler**. I learned this the hard way.

Mistake #2: Using default gamma everywhere
gamma='scale' is okay as a starting point, but it's rarely optimal. Tune it.

Mistake #3: Confusing C and gamma
I thought C controlled the curvy-ness. No – that's gamma. C controls the penalty for mistakes. Different jobs.

Mistake #4: Polynomial with degree=10
Don't do this. The boundary becomes a wiggly mess and training takes forever. Stick to degree=2 or 3.

Part 9: A Word on Ethics (Course Requirement)

We have to talk about responsible AI, so here goes.

When NOT to use SVM:

- Huge datasets (>100k samples) – it's too slow
- When you need to explain why a decision was made (RBF is a black box)
- Very imbalanced classes (use **class_weight='balanced'**)

Bias concern: SVMs learn whatever is in your data. If your training data has historical bias, the SVM will reproduce it. Always test your model on different demographic groups before deploying.

Paper I read: Zafar et al. (2017) tried to make SVMs fairer by changing the math. It works for linear SVMs but gets complicated fast. My take: fairness-aware ML is still an active research area.

Part 10: Accessibility Notes

I tried to make this tutorial accessible to everyone:

- Colour-blind friendly palettes (**viridis** and **cividis**)
- Alt-text descriptions for every figure (for screen readers)
- Clear headings (easy to navigate)
- High contrast (black edges on dots)
- Plain language (no unnecessary jargon)

Part 11: Summary – What I Want You to Remember

Kernel	Best For	Avoid If...
Linear	High-dimensional data, text	Data is clearly tangled
Polynomial	Known curved patterns	You don't know the right degree
RBF	Most real-world problems	You have >50k samples

My final advice to you:

1. Start with linear kernel – it's fast and sometimes works
2. If accuracy is bad, switch to RBF
3. Tune C and gamma using GridSearchCV (don't skip this!)
4. Only use polynomial if you have a specific reason

That's it! Go try these on your own data. You'll thank yourself later.
